## APPENDIX A

## EXTENDED EXPLANATION OF ALGORITHMS

This part further explains the global EDT integration algorithm. In Algorithm 4, the wavefront propagates the distance values in frontierB in GPU hash table GHash. For all neighbors whose distance value can be reduced by cur, we separate them into two streams: For those outside the local volume, we add nbr to frontierB for the next-round propagation; otherwise, we add nbr to frontierC. With frontierC, Algorithm 5 propagates the global observation from the GPU hash table GHash to the local EDT E. This batch of memory within the local volume will is copied to CPU and broadcasted by ROS. On the other hand, the updated portion of the global EDT in the GPU hash table is streamed to the CPU hash table, which adds additional overhead.

## Algorithm 4: PARWAVEFRONT (lower outside)

```
Input: Initial frontiers frontierB, frontiersC, current local EDT
          E, and global EDT in GPU hash table GHash
   Output: Updated local EDT and global EDT
  while frontierB.size \neq 0 do
       CHOOSELEVEL(frontierB)
2
       cur \leftarrow frontierB.pop()
3
       forall nbr \in cur.nbrs do
4
            if nbr \notin E.volume then
5
                if DIST(GHash, nbr) > ||cur.parent - nbr||_2
                     \mathsf{DIST}(GHash, nbr) \leftarrow ||cur.parent - nbr||_2
                     nbr.parent \leftarrow cur.parent
                     frontierB \leftarrow frontierB \cup nbr
            else if DIST(E, nbr) > ||cur.parent - nbr||_2 then
                frontierC \leftarrow frontierC \cup cur
11
12 return E, GHash
```

## Algorithm 5: PARWAVEFRONT (lower inside)

```
Input: Initial frontier frontierC, current local EDT E, and global EDT in GPU hash table GHash
Output: Updated local EDT and global EDT

while frontierC.size \neq 0 do

CHOOSELEVEL(frontierC)

cur \leftarrow frontierC.pop()

forall nbr \in \{x|x \in cur.nbrs \land x \in E.volume\} do

if DIST(E, nbr) > ||cur.parent - nbr||_2 then

DIST(E, nbr) \leftarrow ||cur.parent - nbr||_2

nbr.parent \leftarrow cur.parent

frontierC \leftarrow frontierC \cup nbr

return E, GHash
```

Note that the pseudo-code is written in a sequential fashion for ease of understanding. In actual software, details such as array allocation should be taken care of. At the end of each round of propagation, the new frontier is reconstructed by parallel allocation algorithms. Given several queues localQ on different warps of a thread-block, the algorithm first counts the index of each element using prefix-sum. After that, multiple threads copy elements from the localQ to the frontier for passing in the next-round. Besides, atomic operations are utilized to determine the minimum distance. The implementation details above are not revealed in our pseudo-code.
